### **6.3 Benthic faunal analysis**

#### Summary

Benthic infaunal analysis found no obvious signs of existing impacts on macrobenthic communities at the Doug Pt farm sites or adjacent control sites in the Madford and Tahlee Inlets. Analysis of faunal similarities amongst samples from these sites detected habitat-related variation, with intertidal communities distinct from the subtidal communities. Within the intertidal and subtidal groupings, some differentiation was also observed between farm and control sites, although overlap was observed between these localities, particularly in the subtidal samples. Diversity indices and K-dominance curves revealed no consistent trends in biodiversity or dominance on the basis of habitat, depth or inlet. Communities were generally diverse and exhibited low levels of faunal dominance. The benthic infaunal data gathered in this survey will provide a useful baseline against which future biological change can be assessed.

#### **Methods**

##### Sampling methods

Macroinvertebrates were collected using a Van Veen grab which sampled a 0.07 m<sup>2</sup> area of seabed. A total of three replicate samples were collected at each monitoring site (F1 to F6) and each control site (C1 to C6). The samples were sieved in the field using a 1 mm mesh sieve, and animal and sediment material retained on the sieve placed into vials diluted with 5% buffered formalin. In the laboratory, collected material was washed through a stacked series of sieves (1, 1.4, 2, 2.8 and 4 mm) using the methods described by Edgar (1990). Material retained on each sieve was sorted under a dissecting microscope with animals separated into species groups, counted and placed in labelled vials for long term storage.

##### Analytical methods

Benthic infauna data were analysed using univariate and multivariate statistical methods to assess patterns of spatial variation in the baseline data.

Benthic infauna data were analysed using multidimensional scaling (MDS), as run by SYSTAT (Wilkinson 1989) and PRIMER (Carr 1996) programs, in order to produce the best graphical depiction of faunal similarities among samples. For this analysis, the data matrix showing total abundance of species in each sample was double square root transformed and converted to a symmetric matrix of biotic similarity between pairs of samples using the Bray-Curtis similarity index. These procedures follow the recommendations of Faith *et al.* (1987) and Clarke (1993) for data matrices with numerous zero records. The usefulness of the two dimensional MDS display of relationships among samples is indicated by the stress statistic, which if <0.1 indicates that the depiction of relationships is good, and if >0.2 that the depiction is poor (Clarke 1993).

Several indices were calculated to provide information on macrobenthic diversity at sites sampled:

**Species number, S**

Where S equals the number of species or equivalent taxonomic unit collected in a sample.

**Individuals, N**

Where N equals the number of individuals of all species collected in a sample.

**Diversity (Shannon-Wiener),  $H' = - \sum_i p_i (\log p_i)$**

Where  $p_i$  is the proportion of the total count arising from the  $i$ th species.

**Evenness (Pielou's),  $J' = H'(\text{observed})/H'_{\max}$**

Where  $H'_{\max}$  is the maximum possible Shannon diversity which could be achieved if all species contained the same number of individuals ( $=\log S$ ).

**Richness (Margalef's),  $d = (S-1)/\log N$**

Where d is a measure of the number of species present for a given number of individuals.

In addition, K-dominance curves were calculated for each site sampled, based on pooled replicate data. K-dominance curves rank the families collected at each site from most abundant to least abundant and allow easy determination of levels of faunal dominance. K-dominance curves provide a useful indicator of benthic infauna community health, with large y-intercept values and steep curves indicative of high levels of faunal dominance and hence low levels of community health.

Results and interpretation

Macrofauna species collected during the survey are shown in Table 8.7.1 and

Table 8.7.2 and consisted of 154 species represented by a total of 1159 individuals. Samples from the six farm sites at Doug Pt included 119 species and 543 individuals, whilst the remaining 616 individuals, representing 105 species, were identified in samples from the control sites. The samples were dominated by polychaete worms (62 species, 633 individuals), crustaceans (48 species, 348 individuals) and molluscs (29 species, 88 individuals), while echinoderms, nemerteans, anthozoans and a range of less common taxa were also identified. The most common species were the polychaete worm *Scyphoprocus* sp. (163 individuals) and the tanaid crustacean *Kalliapseudes* sp. (77 individuals, with the decapod crustacean Grapsid sp. (35 individuals), isopod crustacean Anthurid sp. (40 individuals), ophiuroid echinoderm *Ophiactis* sp. (32 individuals) and polychaete worms *Glycera cinnamomea* (37 individuals) and *Diopatra* sp. (34 individuals) also relatively common. All of these species were distributed across both farm and control sites. Species diversity was similar to that found in studies carried out by Aquenal for Marine Harvest of six other mangrove estuaries but abundance was about half that found in five of those estuaries and 70% of the sixth.

The results of MDS analysis using all macrobenthic samples are displayed in Figure 6-7. The MDS plot reveals differences between intertidal and subtidal samples, since the former are grouped on the left side of the plot, with the latter on the right side. The only exception was F3, an intertidal farm site that showed a higher level of similarity with certain subtidal sites than with the remaining intertidal sites. Within-site similarity was highly variable, since triplicate samples from some sites formed tight groupings in the MDS plot (e.g. F2, C2, C6), whilst others were widely dispersed (e.g. F1, F3, F4, C4). Within the intertidal and subtidal groupings, there was no clear separation of samples on the basis of the inlet from which they were collected.

The stress statistic for the MDS plot in Figure 6-7 exceeds 0.2 and therefore reflects a relatively poor depiction of patterns of similarity among samples. The data were therefore re-analysed on the basis of pooled replicate samples for each site, with the results provided in Figure 6-8. In this case, the stress statistic of 0.12 reflects an accurate depiction of relationships among sites. The separate groupings of intertidal and subtidal sites were again distinct, with intertidal sites grouped on the left and subtidal sites on the right. On the basis of grouped samples, the benthic infauna at site F3 displayed a higher similarity with other intertidal sites than they did in the MDS analysis of triplicate samples (Figure 6-7). Analysis of pooled samples also revealed more distinct groupings on the basis of geographical locality. Intertidal farm sites (F1-F3), collected from Geranium Channel and Phoenix Inlet, were located in the top half of the MDS plot, while intertidal control sites (C1-C3), collected from Madford Inlet and Tahlee Inlet, were located in the bottom half. Similarly, subtidal farm sites formed a grouping in the bottom right section of the MDS plot, however subtidal control sites were more dispersed due to differentiation of C6, the deepest control site. The two deepest farm sites, F5 and F6 (13 m and 12.1 m depths respectively), showed a high level of similarity and had faunas similar to those at a shallower control site (C5, 6.2 m). Within the subtidal sites, the benthic infauna communities therefore displayed no clear differentiation on the basis of depth.

Overall, patterns of similarity amongst macrobenthic samples reflected a mixture of habitat (intertidal/subtidal) variation and geographical separation of the farm and control localities. The taxa that accounted most for differences in assemblages

between intertidal and subtidal sites were the polychaete worm *Scyphoprocus* sp. and decapod Grapsid sp., which were considerably more abundant at intertidal sites, and the tanaid *Kallipseudes* sp. and isopod Anthurid sp., which were more common at the subtidal sites. At the subtidal sites, *Kallipseudes* sp. and Anthurid sp. were less common at the farm sites than at control sites and contributed most to the grouping of subtidal farm sites in the MDS plot. The control site C6 was separated from other subtidal sites in the MDS plot due to higher numbers of *Kallipseudes* sp. and Anthurid sp. and, in particular, the polychaete worm *Diopatra* sp.

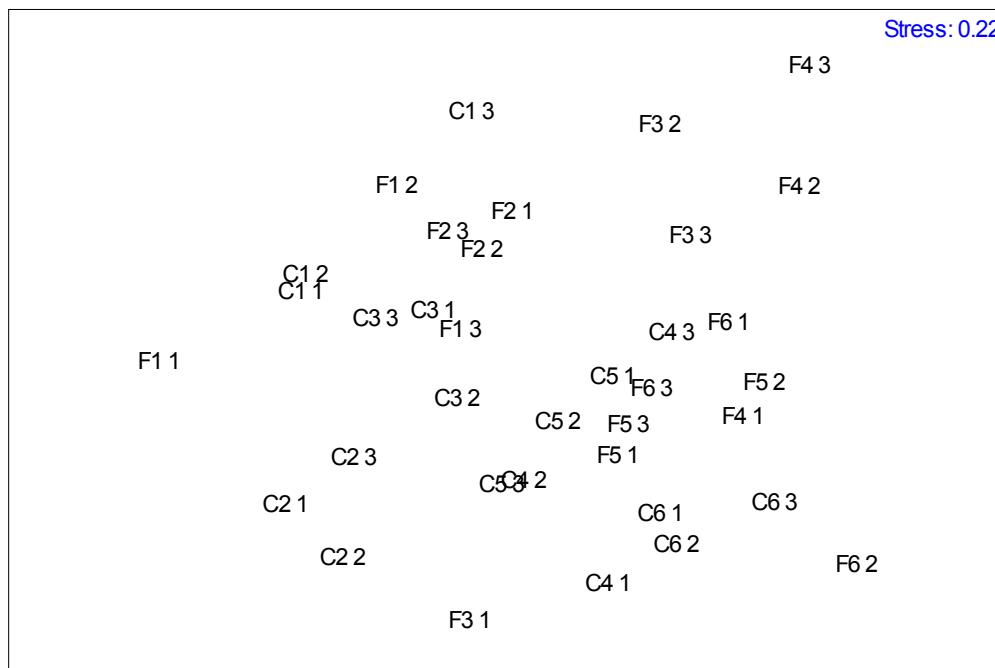

Figure 6-7 Results of MDS analysis using macrobenthic data from triplicate samples at each site.

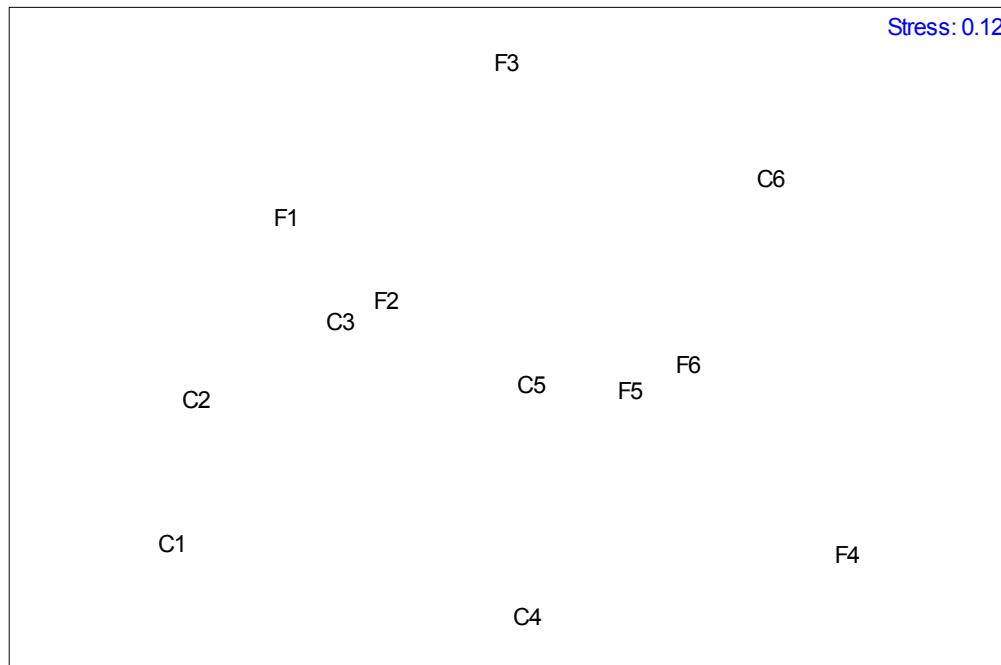

Figure 6-8 Results of MDS analysis using pooled replicate macrobenthic data from each site.

The results of diversity indices calculations are provided in Figure 6-9 and provide baseline data that can be readily compared with future data to assess temporal variation in biodiversity. Species and individual numbers peaked at intertidal sites C3 and F1, while high animal numbers, and to a lesser extent species numbers, were also recorded at subtidal sites C5 and F5. Both animal and species numbers were consistently low at intertidal sites C1 and C2 and subtidal sites C4 and F4. These patterns of variation were present but less pronounced in the Shannon–Wiener diversity index ( $H'$ ) and Margalef's richness index ( $d$ ) values, with consistently high values at C5 and F5, and lower values at C4 and F4. For these indices, there was no clear relationship between diversity and habitat, depth or inlet, although the deepest farm and control sites (C5, F5 and F6) recorded consistently high or moderate-high values. Pielou's evenness index ( $J'$ ), which reflects how evenly the numbers of individuals are distributed amongst species, recorded similar values at all sites, with the exception of slightly reduced evenness values at sites C3, C4, and F1. Reduced evenness at these sites can be explained in part by very high numbers, relative to other species, of *Scyphoproctus* sp. at C3 and F1 and of *Kalliapseudes* sp. at C4.

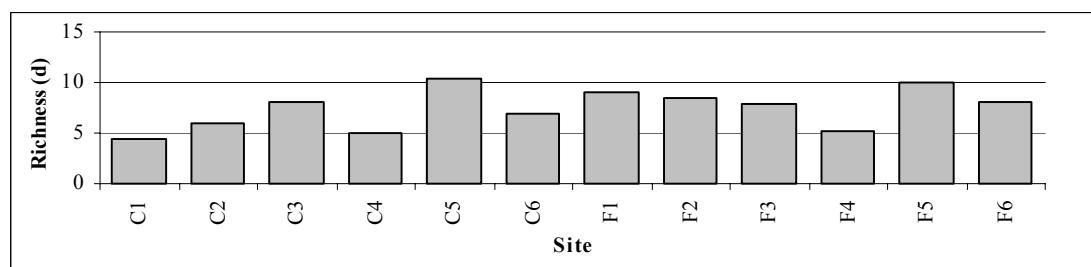

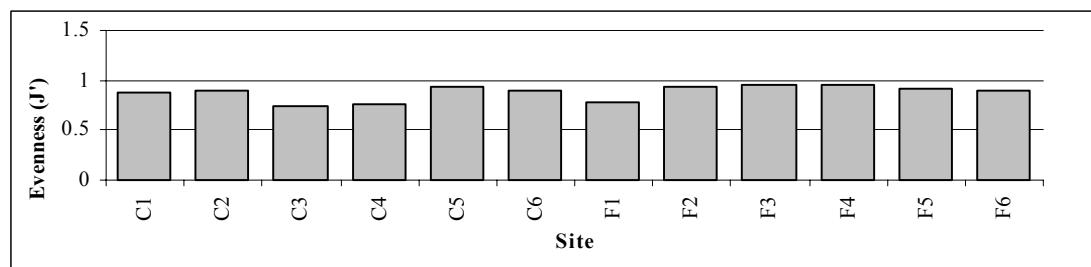

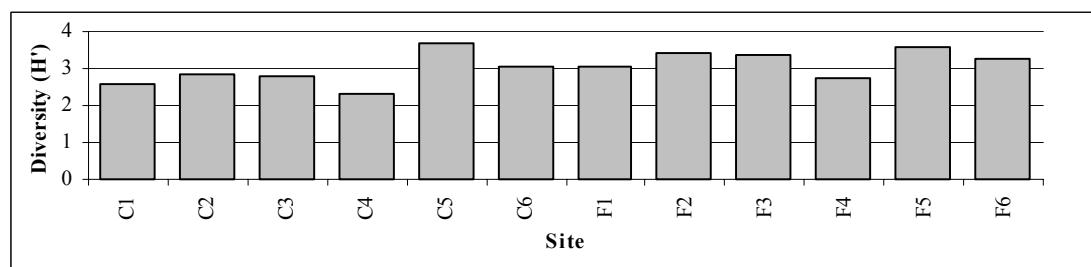

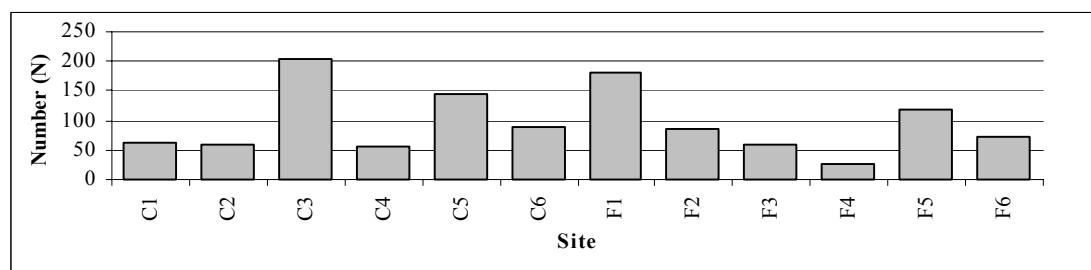

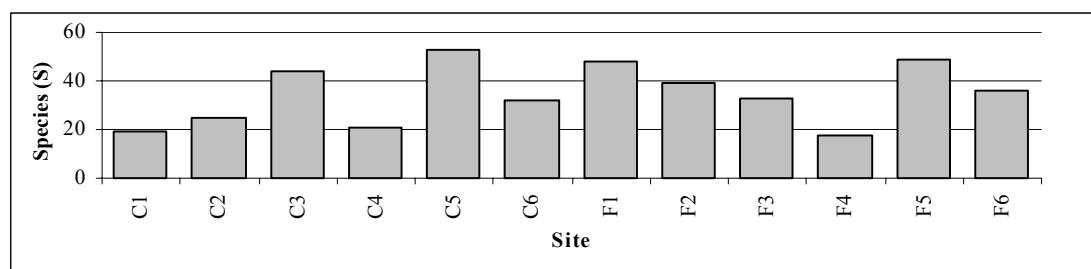

Figure 6-9 Macrobenthic diversity indices for farm and control sites; S = number of species, N = number of individuals,  $H'$  = Shannon-Wiener diversity index,  $J'$  = Pielou's evenness index, d = Margalef's richness index.

K-dominance curves for pooled replicate samples at each site are presented in Figure 6-10. At the majority of the sites the y-intercept values reflected low levels of faunal dominance, with the most dominant species comprising ~20% or less of animal numbers. At a smaller number of sites (C3, C4, F1), the most dominant species comprised ~30-40% of animals collected, reflecting a slightly higher level of dominance. However, remaining components of the assemblages consisted of a large number of low abundance species, particularly at C3 and F1, reflecting low levels of dominance overall. F1, in addition to having an elevated y-intercept value, had higher dominance than other sites across the 2<sup>nd</sup>-7<sup>th</sup> most common species and had a reduced total number of species, as shown by the elevation of the F1 curve in the plot. Conversely, the subtidal control site C5 had the lowest y-intercept value, lowest dominance levels across species of all ranks and possessed the highest number of species overall, reflecting a very low level of dominance. None of the K-dominance curves depicted in Figure 4 are indicative of high levels of pollution or other forms of environmental degradation, and there was no clear relationship between dominance levels and habitat, depth or inlet.

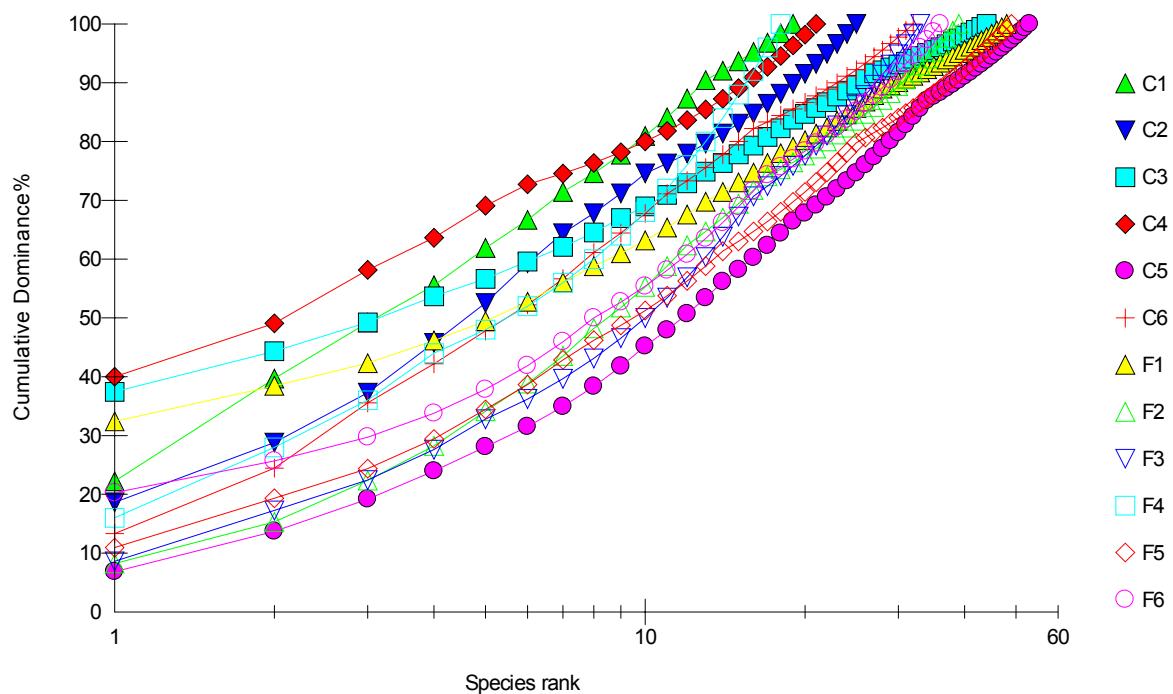

Figure 6-10 K-dominance curves for pooled replicate macrobenthic samples at each site
